Detailed image of the entire crust and Moho discontinuity in the area of the Baltic basin, N Poland, were derived from reprocessing several 2D Vibroseis industry seismic reflection profiles with the use of the extended-correlation technique. We apply this method to a subset (5 profiles of 950 km total length) of ION Geophysical PolandSPANTM regional seismic program covering the marginal region of the East European Craton (EEC) and originally aimed at imagining Lower Palaeozoic shale play over entire country.

Given the raw, uncorrelated seismic data, acquired with a 28-s listening time and 16-s long sweep, we were able to extend the nominal record length up to 22 s two-way-time (TWT) (~ 60 km depth). For the recorrelated dataset, we designed a special processing workflow including denoising, cascade deconvolution, signal enhancement, frequency filtering and post-stack migration. In order to boost signal coherency, common-reflection surface (CRS) stacking was also tested here, however for this high-fold data, the improvement in events' continuity does not justify long computation time. On the other hand, significant uplift in clarity of the deeper events was obtained by applying segment migration technique (Calvert 2004). In order to support interpretation of the final results, we performed a time-depth conversion of the post-stack migrated sections using velocity model compiled from the available pre-stack depth migration velocity models for the section above the basement and the velocity field based on a recent compilation of the wide-angle reflection/refraction (WARR) profiles for the deeper section below the basement.

Processing of the strike lines (i.e. perpendicular to the Teisseyre-Tornquist Zone, TTZ) revealed a very reflective lower crustal domain. Previously, reflective lower crust was noted in the legacy deep reflection seismic data from the Pomerania region, as well as in the new reflection seismic profiles further south along the TTZ in Poland (profiles from the same PolandSPANTM family as well as the POLCRUST profile). We tentatively link this reflectivity with the passive-margin stage of Baltica. Moho reflectivity varies in strength and quality, but is observed across the profiles at a consistent depth level of ca. 35-40 km, which is roughly compatible with the observations from WARR data. Some interesting reflectivity patterns were also observed close to the Mesoproterozoic (1.5 Ga) anorthosite-mangerite-charnockite-granite (AMCG) complexes (Skridlaite et al. 2003), which may contribute to solving the problem of their emplacement in the crust.

This study was funded by the Polish National Science Centre grant no UMO-2015/19/B/ST10/01612. Thanks to A. Calvert for providing his segment migration code.
